NATIONAL FUSION FACILITY

UC SanDiego
Disruptions result in rapid loss of plasma thermal and magnetic energy

- Disruption is a global MHD instability which terminates the tokamak discharge
  - Caused by crossing stability boundary or by control/power system failure
  - Three main phases:
    - Precursor
    - thermal quench (TQ)
    - current quench (CQ)
  - Large toroidal electric field during CQ can create runaway electrons

Disruption time sequence

- $B_{\text{dot}}$ (T/s)
- $T_e$ (keV)
- $I_p$ (MA)
- $E_{\phi}$ (V/m)

EM Hollmann APS DPP, XI3.00004, November 6, 2009
Rapid loss of plasma thermal and magnetic energy during disruption can damage walls

- Divertor heat loads (TQ)
- Vessel forces (CQ)
- Runaway electrons (CQ)

Thermography of DIII-D outer strike point during disruption

Shutdown by impurity injection reduces wall damage compared with unmitigated disruptions.

- Cause rapid shutdown by massive impurity injection into main chamber (gas injection, pellet injection)
  - Reduced divertor heat loads by radiating thermal energy into main chamber
  - Reduced halo currents by making plasma more resistive and shutting down before plasma drifts into wall
  - Improved runaway electron avoidance by collisional drag on runaways?

Fast bolometry of massive D₂ gas injection into DIII-D
Rapid shutdown to be used as last resort in ITER

1) Avoid disruptions by avoiding stability boundaries and control system failures

2) If disruption should occur, attempt “soft landing” (current rampdown, turn off heating, etc)

3) As last resort, use preemptive rapid shutdown
   - Presently envision using massive gas injection (MGI) in ITER: 2 ports allocated
   - Alternate rapid shutdown methods being considered
Massive gas injection works well in present tokamaks

- Massive gas injection (MGI) has been successfully implemented on many tokamaks (DIII-D, C-MOD, JET, ASDEX-U, etc.)
- MGI gives reliable heat load and halo current reduction compared with disruptions
- MGI heat load and vessel force reduction is expected work in ITER also. RE characteristics still uncertain

**DIII-D divertor heat loads from disruptions vs MGI shutdown**

**DIII-D vessel currents reduced by MGI shutdown**

EM Hollmann APS DPP, XI3.00004, November 6, 2009
Rapid shutdown gives wide range of runaway electron levels in DIII-D

- Very small RE current in normal disruptions ($I_{RE} < 1 \text{ A}$)
- Significant RE currents with Ar pellet shutdown
- Very small ($I_{RE} < 1 \text{ A}$) RE current with low-Z (He, D$_2$, or H$_2$) MGI
- In ITER, larger RE avalanche gain ($>10^{10}$ in ITER vs ~50 in DIII-D), so even a 1 A seed could be dangerous!

EM Hollmann APS DPP, XI3.00004, November 6, 2009
Sufficiently massive particle delivery could achieve complete runaway electron suppression

- Complete suppression of RE formation predicted to occur at total electron density $n_{\text{tot}} \sim n_{\text{crit}} \sim 4 \times 10^{16}/\text{cm}^3$ in plasma current channel [Rosenbluth, 1997]
- DIII-D investigating three different massive particle delivery methods (massive gas injection, large shattered pellets, shell pellets)
- Uniform deposition of large densities challenging due to short (< 1 ms) TQ
  
  1) Large pellet hits edge
  2) Pellet hits q=2, starts TQ
  3) Pellet continues on during CQ

Large solid pellet is not considered, because ...

Incomplete impurity deposition due to TQ onset:
Massive gas injection

- Fire short (~2 ms) pulse of high pressure gas into plasma
- To optimize delivery before TQ onset, want fast pressure rise
- Best results obtained by simultaneously firing multiple small valves

**MGI system overview**

**6-valve MGI flange**

EM Hollmann APS DPP, XI3.00004, November 6, 2009
Large shattered pellets

- Intermediate between gas injection (no penetration into plasma) and single large pellet (goes all way through plasma)
- Fire large frozen pellet into shatter plate to break into ice shards [Jernigan, JP8.00090]
Shell pellets

- Shell pellet concept is to surround dispersive payload with thin low-Z shell which burns off in plasma edge

- Have tried small shell pellets \((D = 2 \text{ mm polystyrene filled with boron powder or } 10 \text{ atm Ar gas})\) and large shell pellets \((D = 1 \text{ cm polystyrene filled with boron powder})\)
Massive impurity injection methods typically give ~ 5-10% of desired mass deposition.

- Highest 0D mid-CQ \( n_{\text{tot}}/n_{\text{crit}} \sim 14\% \) achieved using 5 valve He MGI
- Highest local \( n_e \) achieved with shattered D\(_2\) pellet in TQ
- Large shell pellet payload not released (deposition from shell only)

\[ \frac{n_{\text{tot}}}{n_{\text{crit}}} \text{ in middle of CQ.} \]
Impurity delivery of massive gas injection limited by finite gas flow rise time

- TQ MHD destabilizes when MGI-induced edge cold front propagates in radially to $q \sim 2$ (takes $\sim 1$ ms)
- During TQ, efficient mixing (20% or more) of edge impurities into core
- Later-arriving (during CQ) gas not well-assimilated

**Short (~1-2 ms) pulse MGI**

- $N_{core}$ (mid CQ) vs. Number injected in 1st ms ($10^{22}$ atoms)
- $H_2$, $D_2$, $He$, $Ne$, $Ar$

**Long (~10-15 ms) pulse MGI**

- Total number injected ($10^{22}$ atoms)
- 2005 (Ar) and 2006 (Ar)
Large shattered D$_2$ pellets give faster, more direct impurity deposition than gas injection

• Fast camera images show D$_2$ ice shards depositing particles rapidly and less localized to port than MGI

Fast camera images of He MGI shutdown

Images of shattered D$_2$ pellet shutdown
Large shattered D$_2$ pellets achieve very high local density during TQ

- Electron density measured with different diagnostics at different toroidal locations
- Extremely large n$_e$ ~ 7x10$^{15}$/cm$^3$ observed transiently at injection port
- During CQ, density becomes lower and more isotropic toroidally [Commaux, UOP. 00004]
- Mid-CQ density similar to MGI
- Ideally, would like to have high density throughout CQ
Need to design large shell pellet which will release payload during thermal quench

- Small ($D = 2\,\text{mm}, t = 0.4\,\text{mm}$) shell pellets successfully demonstrated burn-through and payload deposition in plasma core
- Large ($D = 1\,\text{cm}, t = 0.4\,\text{mm}$) polystyrene shells passed through plasma - shell made too thick!
- Initiated thermal quench at $q = 2$ surface
0D simulations ignoring radial loss of heat or particles

For MGI, assume $L = 5$ m, $D = 2$ cm delivery tube, 10 ms pulse, and 20% TQ mixing efficiency

For ‘ideal’ deposition assume all impurities deposit in 1 ms pulse with 100% efficiency

Ideal deposition achieves $n_{\text{tot}}/n_{\text{crit}} > 1$ for sufficiently massive deposition

MGI doesn’t achieve $n_{\text{tot}}/n_{\text{crit}} > 1$ even for 50 valves

Ideal deposition of impurities expected to achieve collisional runaway suppression in ITER
Disruption runaway electron studies

- Achieving $n_{\text{tot}}/n_{\text{crit}} > 1$ throughout the ITER volume may be challenging.

- Important RE questions:
  - Is $n_{\text{tot}}/n_{\text{crit}} > 1$ really necessary for RE suppression?
  - How large will RE seeds be in ITER during rapid shutdown?
  - Can RE confinement be influenced with external magnetic fields?

- Pursuing RE studies with dedicated experiments and new diagnostics
  - RE synchrotron imaging
  - RE gamma scintillator array

Gamma scintillator

EM Hollmann APS DPP, XI3.00004, November 6, 2009
Runaway electron beams observed via visible synchrotron emission

- Strong ($I_{RE} \sim I_p$) RE beams can be created by Ar pellet injection and imaged with visible camera [Yu, JP8.00096]
- RE beam consistently seen to drift into upper divertor
- RE location well-described by JFIT flux contours (white lines)

Visible/near-IR fast camera movie

EM Hollmann APS DPP, XI3.00004, November 6, 2009
Runaways lost to wall in 3 phases

- Runaways give gamma flashes ($\varepsilon > 0.5$ MeV) upon hitting wall
- Strong prompt loss flash of REs lost into lower divertor at start of CQ
- Weaker loss of REs into main chamber wall during CQ
- Strong late loss flashes when RE beam drifts into wall at end of CQ
- Toroidal structure seen in late loss [James, JP8.00095]
Presence of prompt runaway loss consistent with NIMROD simulations

- RE transport in DIII-D fast shutdowns simulated with NIMROD 3D MHD code
- A beam of REs can remain on good flux surfaces in core [Izzo, CO4.00010]
- After TQ, many REs are lost along destroyed flux surfaces to lower divertor

NIMROD simulation of ideal (0D deposition) Ar rapid shutdown in DIII-D

42 electrons confined, 197 lost

EM Hollmann APS DPP, XI3.00004, November 6, 2009
Estimated avalanche growth time ~ 2 ms consistent with 0D model

- In large RE current shots, can estimate RE current from shape of $I_p$ vs time
- 0D estimate of avalanche growth time ~ 2 ms consistent with data
- Only free parameter is size of seed term; RE seed appears to be ~ 8 kA in this shot, giving ~ 50x gain from avalanching

![Graph showing I_p, E_φ, and I_RE over time](image)
Negligible runaway seed term predicted during CQ from 0D model

- Standard Dreicer model for RE seed: $\gamma_{RE} \sim \exp(-E_{Dreic}/E_\phi)$
- 0D Dreicer seed would appear during CQ
- Minimum predicted value of $E_{Dreic}/E_\phi \sim 10^2$, too large for measurable Dreicer seed!
- Possible explanations for measured RE seed
  - Local effect (1D or 2D)?
  - Time-dependent effect (hot-tail seed)?
  - Magnetic reconnection?
Negligible runaway seed term predicted during pre-TQ phase from 1D model

- Before TQ MHD, can use 1D current diffusion model to estimate $E_{\phi}$

- Model predicts peak with enhanced $E_{\phi}$ at cold front

- 1D TQ Dreicer seed larger than 0D CQ model, but still negligibly small

EM Hollmann APS DPP, XI3.00004, November 6, 2009
Estimates of RE energy can be made from synchrotron brightness and shielded scintillator array.

Data gives peak RE energy around 30-40 MeV, slightly lower than 50-60 MeV from 0D model.

Measured peak runaway energy roughly consistent with 0D model.
Deconfinement of weak runaway beams seen with applied $n = 3$ perturbation

- Possible supplement to MGI is applied magnetic perturbation to deconfine REs
- Observing deconfinement challenging because of high variability in RE seed term
-Appear to see enhanced deconfinement with $n = 3$ field applied to weak RE beams [Humphreys, JP8.00091]

- Trend is not clear in case of $n = 1$ perturbation or with strong RE beams
Summary

- DIII-D has developed unique new rapid shutdown capabilities to study feasibility of achieving collisional RE suppression
  - Multi-valve massive gas injection
  - Shattered massive cyrogenic pellet injection
  - Large shell pellet injection
- Presently, have achieved $n_{\text{tot}}/n_{\text{crit}} \sim 14\%$ with multi-valve He MGI
- DIII-D has developed new diagnostics for RE studies
  - Visible synchrotron imaging
  - Gamma scintillator array
- RE amplification and acceleration matched with 0D models
- Disruption RE seed term in DIII-D experiments not understood yet
- Applied magnetic perturbations for deconfining RE seeds show promising preliminary results
Future plans

- Improved understanding of RE formation, amplification, and loss, including effect of magnetic perturbations
- Continue massive impurity deposition experiments (massive gas injection, shattered pellets, shell pellets)
- Attempt to control RE beam with feedback control
- Fire pellets through REs for RE beam diagnosis and mitigation
- Improved modeling and predictive capability
Fast bolometry shows that impurities are mostly still localized to injection region at TQ onset for MGI.

For shattered pellet, TQ impurity deposition appears to be throughout plasma.

TQ duration appears to be significantly (~2x) faster for shattered pellet shutdown than D$_2$ MGI, consistent with more direct impurity deposition.
Shell ablation rate fairly well-predicted for small pellets

- Strong shielding [Parks, 1998] and medium shielding [Sergeev, 2006] ablation models work reasonably well for small polystyrene shell; worse for large polystyrene shell.

Measured vs predicted polystyrene shell burn-through
Large scatter in runaways created appears to be due to seed term variation

- Late-loss gamma scintillator flash good qualitative measure of RE current.
- Non-thermal ECE best measure of early confined RE population - late RE current scatter ~ 10x relative to early population.
- Early loss RE also ~ 10x scatter relative to late RE population.
- Suggests that early RE loss fraction and CQ RE amplification are not varying by 3 orders of magnitude shot-shot.
